| <b>Abstract:</b>                                     | <p>In tourist destinations with limited road and parking capacities, seasonal surges in private vehicle traffic often cause external diseconomy, including congestion and traffic calming issues. Conventional infrastructure-based solutions for tourist parking management are frequently too large or inflexible to address spatially and temporally localized problems effectively. This study investigates a compact, deployable parking guidance system designed to mitigate traffic issues caused by private tourist vehicles accessing a narrow street. A field experiment was conducted in Apr 2025 at Higashi-Hazu Beach, Nishio City, Japan. A real-time vehicle counting system is developed for an ungated seaside parking lot using only two roadside Light Detection and Ranging (LiDAR) sensors to monitor the entries and exits at access points. Accuracy validation against video recordings confirms consistent detection performance even under high-traffic and mixed pedestrian conditions. To proactively guide drivers, a Variable Message Sign (VMS) dynamically displays the congestion status (“Congested”, or “Full”) at a key intersection preceding a narrow access street. The display content is automatically updated based on real-time vehicle counts obtained from the LiDAR sensors. Comparative analysis between periods with and without the VMS reveal a significant increase in vehicles diverting to a fringe parking lot during "Congested" conditions when the sign is active. This study demonstrates that a compact and deployable LiDAR-based guidance system can affect driver behavior and contribute to more sustainable parking management in tourism-heavy regions, mainly in areas where the conventional methodology is too extensive to implement.</p> |                         |

## Abstract

In tourist destinations with limited road and parking capacities, seasonal surges in private vehicle traffic often cause external diseconomy, including congestion and traffic calming issues. Conventional infrastructure-based solutions for tourist parking management are frequently too large or inflexible to address spatially and temporally localized problems effectively. This study investigates a compact, deployable parking guidance system designed to mitigate traffic issues caused by private tourist vehicles accessing a narrow street. A field experiment was conducted in Apr 2025 at Higashi-Hazu Beach, Nishio City, Japan. A real-time vehicle counting system is developed for an ungated seaside parking lot using only two roadside Light Detection and Ranging (LiDAR) sensors to monitor the entries and exits at access points. Accuracy validation against video recordings confirms consistent detection performance even under high-traffic and mixed pedestrian conditions. To proactively guide drivers, a Variable Message Sign (VMS) dynamically displays the congestion status ("Congested", or "Full") at a key intersection preceding a narrow access street. The display content is automatically updated based on real-time vehicle counts obtained from the LiDAR sensors. Comparative analysis between periods with and without the VMS reveal a significant increase in vehicles diverting to a fringe parking lot during "Congested" conditions when the sign is active. This study demonstrates that a compact and deployable LiDAR-based guidance system can affect driver behavior and contribute to more sustainable parking management in tourism-heavy regions, mainly in areas where the conventional methodology is too extensive to implement.

This study includes the results of the Cross-ministerial Strategic Innovation Promotion Program (SIP) 3rd Phase, "Development of Smart Mobility Platform," promoted by the Council for Science, Technology, and Innovation, Cabinet Office. Project Management Agency: New Energy and Industrial Technology Development Organization (NEDO) (Project Code JPNP23023).

## 1 Introduction

Tourism demand plays a crucial role in urban economic activity. In Tokyo, Japan, domestic visitors contribute approximately 84 trillion Japanese Yen (JPY) to the annual economic output [1]. Similar impacts were observed in non-metropolitan areas. For example, several regions in Shizuoka Prefecture, Japan, are estimated to generate over 80 billion JPY in tourism demand [2].

Investments aimed at attracting tourists positively affect the number of visitors. Particularly effective are investments in information provision and improvements to secondary transportation systems [3]. A correlation between accessibility and economic benefits has also been observed in other regions. Mexico's "Magic Town" initiative found that areas with higher accessibility tended to experience more substantial financial benefits by consuming complementary tourism services [4].

However, an excessive concentration of tourism demand can result in an external diseconomy for local communities. This phenomenon has long been recognized, and the term "overtourism" was introduced to describe it in the early 2000s [5]. The World Tourism Organization (UNWTO) defines over-tourism as "the impact of tourism on a destination, or parts thereof, that excessively influences the perceived quality of life of citizens and/or quality of visitors' experiences in a negative way" [6]. However, when there is limited congestion disutility for tourists, they may be unaware of this issue [7]. It is essential to implement balanced measures that allow communities to benefit from tourism, while maintaining a livable environment and ensuring sustainability.

One such approach is to apply the Tourism Carrying Capacity (TCC). In a simulation study using digital data from Dubrovnik, the mobility and transportation facilities were identified as subsystems with capacity constraints [8]. Various strategies have been proposed to address

1 limited transport capacities. For example, in congested  
2 tourist destinations, stated preference surveys have shown  
3 that introducing new mobility services can reduce the  
4 share of private car usage to < 20% [9]. However, parking  
5 remains an important issue. There is evidence that  
6 expanding parking facilities in response to tourist demand  
7 can undermine the mobility of residents [10].

8  
9 Parking policy studies have involved extensive  
10 perspectives, such as economics [11] and connections to  
11 land-use policies [12]. Among these, the provision of  
12 information remains a significant focus. Many studies  
13 have hypothesized that providing parking information  
14 influences parking lot choice behavior and reduces  
15 cruising time. These effects have been modeled and  
16 generalized [13] [14], and simulations have suggested that  
17 dynamic information provision can reduce cruising times  
18 by up to 17% [15]. Empirical demonstrations have also  
19 been conducted. A pilot project in Nottingham, UK,  
20 provided static parking information through newspaper  
21 advertisements and real-time information via radio  
22 broadcasts. The results showed that drivers who received  
23 this information were more likely to choose peripheral  
24 park-and-ride facilities instead of parking in the city  
25 center [16].

26  
27 Although some proposals monitor visitor flows in  
28 tourist areas, using a combination of pyroelectric sensors  
29 and survey data. One example is the application of 39  
30 pyroelectric sensors, which requires extensive equipment  
31 and infrastructure [17]. Such methods may be excessive  
32 when addressing spatially and temporally localized issues.  
33 Detecting the number of parked vehicles in parking lots  
34 with gates or marked spaces is relatively straightforward.  
35 However, in ungated lots where vehicles park in an ad-  
36 hoc manner, traditional methods, other than manual  
37 counting, struggle to yield accurate counts.

38  
39 However, in recent years, advances in autonomous  
40 driving technologies have made it possible to use Light  
41 Detection And Ranging (LiDAR)-based sensing systems  
42 to detect the vehicle size, direction, and speed in real-time.  
43 Previous studies counted vehicle passages with an  
44 accuracy of 83–94% [18]. Applying this technology to  
45 detect the total number of vehicles within a parking area  
46 enables real-time parking management, even for ungated  
47 lots, with smaller and more mobile sensing infrastructure  
48 than conventional systems.

49  
50 This study focuses on the Higashi-Hazu Beach in  
51 Nishio City, Japan, where local overtourism due to private  
52 car use has been an issue, particularly during peak seasons,  
53 and countermeasures have been insufficient. A real-time  
54 vehicle counting system is implemented using LiDAR  
55 and its accuracy is evaluated along with a dynamic  
56 guidance system using a Variable Message Sign (VMS)  
57 to guide drivers based on parking situations. This study  
58 aims to verify whether such a compact and mobile system

can effectively guide behavior in tourist spots that have  
struggled with effective parking management.

## 2 Methodology

### 2.1 Target District

This study focuses on the Higashi-Hazu Beach, located  
in Nishio City, Japan. The beach lies within the Nagoya  
metropolitan area, approximately 60 km from the center  
of Nagoya.

Higashi-Hazu Beach is a popular destination for  
recreational clamming, particularly during Japan's long  
holiday period from late Apr to early May, attracting  
many tourists who travel via private vehicles.

However, this beach is in a traditional fishing village  
with narrow streets. The parking area adjacent to the  
beach has limited capacity, and no system exists to  
provide real-time occupancy information. These parking  
spaces lack gates and marked stalls, making it impossible  
to track the number of parked vehicles in real-time using  
conventional methods. Consequently, even when seaside  
parking is full, drivers continue to enter the area in search  
of parking despite the availability of fringe parking  
facilities located outside the narrow streets. This behavior  
leads to various issues, including traffic deadlocks owing  
to vehicles being unable to pass each other, conflicts  
between cars and pedestrians, and problems in residential  
environments.

### 2.2 Real-Time Vehicle Detection Using LiDAR Sensors

To address these issues, a field experiment was  
conducted involving the following components. Figure 1  
illustrates the structure of the system tested in this study.

In this seaside area, individual parking spaces are not  
clearly defined, making it unfeasible to obtain occupancy  
for each space using cameras or similar devices. Counting  
vehicles within an area rather than per lot is more  
appropriate. Since the parking area spans multiple zones,  
installing gates at the entrances is not a viable option, as  
doing so would require installing them on public roads.

Instead of gates, an effective approach to counting  
vehicles is to define cordon lines at the points where  
vehicles enter and exit. Manual observation is costly,  
while camera-based monitoring raises privacy concerns  
due to the retention of video footage. Furthermore, camera  
detection accuracy can deteriorate under varying sunlight  
intensity and angles, although recent advancements in  
detection technologies have mitigated this issue to some  
extent [19][20]. Considering these factors, LiDAR  
technology offers a promising solution, as it enables  
unmanned observation without recording images and is  
less affected by sunlight conditions.

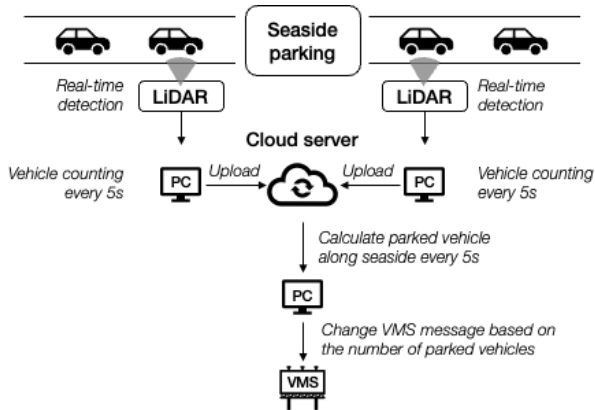

Figure 1. Sensing and calculation system structure

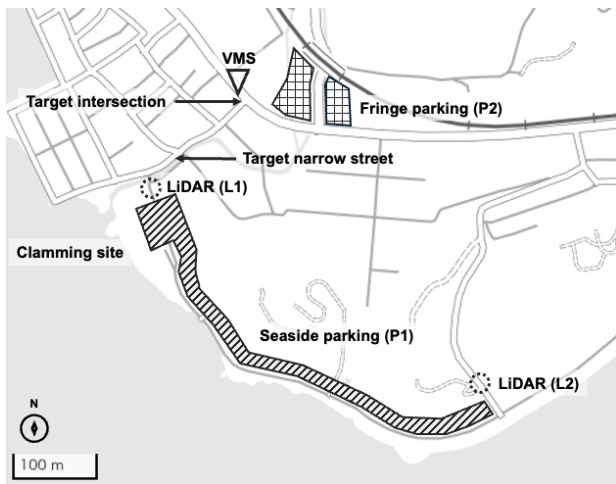

Figure 2. Field experiment site and the location of each device

First, to enable real-time monitoring of the number of vehicles in the seaside parking area, LiDAR sensors were installed on two access routes to the beach (locations L1 and L2 in Figure 2) (Figure 3). An algorithm developed by the authors enabled the automatic detection of the number of passing vehicles based on the data collected from these roadside LiDAR units. As the targeted streets are narrow and do not have lane separation by direction, the algorithm was further enhanced to detect vehicle direction and distinguish vehicles from pedestrians. These enhancements represent technical advancements from previous studies [18].

Each computer connected to a LiDAR sensor aggregated the number of passing vehicles in each direction every 5 s to estimate the net number of cars entering or exiting each monitoring point.

The calculated results from each computer were transmitted to a cloud server in real-time via mobile communication. By aggregating these data on the server, the number of vehicles in the seaside parking area (P1 in Figure 2) was computed every 5 s in real-time. Instead of detecting occupancy at the level of individual parking spaces, vehicle counts were derived based on entries and

exits, significantly reducing the number of sensors required.

A computer connected to the VMS receives the resulting data from a cloud server via mobile communication. Based on this information, the VMS display was automatically updated as described in the following section.

Figure 3. Roadside LiDAR equipped at location L2

Figure 4. VMS at the target intersection displaying "Seaside Full"

### 2.3 Guidance with Real-Time Information on the Variable Message Sign

In this study, a VMS was installed at the intersection of the narrow street and the seaside parking area. Based on the real-time vehicle count, the VMS displayed either "Seaside Congested" or "Seaside Full" (Figure 4). Although the seaside parking area does not have a clearly defined parking capacity, an approximate capacity of 320 vehicles was assumed, based on the analysis presented in this study.

Thresholds followed the capacity of the seaside parking area: "Seaside Congested" was displayed when

the number of vehicles was > 170 (approximately 50% of the capacity), and "Seaside Full" was displayed when the vehicle count was > 240 (approximately 75% of the capacity). These thresholds were defined based on manually collected vehicle count data from the previous year.

While the 75% threshold for the "full" status may initially appear low, it should be noted that the estimated capacity of 320 vehicles includes those moving along the seaside road to find an available parking lot. Therefore, when the number of cars reaches 240, the seaside parking area is already experiencing significant congestion, and it becomes challenging to find a new parking space, except at locations far from the clamming site.

As illustrated in Figure 1, the VMS was connected to the internet to automatically update the display based on sensor input. A temporary fringe parking lot is available outside the narrow street (P2 in Figure 2). Therefore, the message on the VMS was updated to instruct drivers divert to this alternative lot, thereby reducing traffic on the narrow street (target narrow street in Figure 2).

The experiment was conducted over five days from 26 Apr to 30 Apr 2025, coinciding with the peak clamming season. During this period, the VMS unit was operational for three days and deactivated for two days, allowing for comparative analysis. Additionally, video cameras were installed at the target intersection, enabling observation of driver behavior to assess the effect of the VMS guidance.

### 3 Results

#### 3.1 Vehicle Count Observations

Vehicle counting was conducted for five days during the experiment (Table 1). The peak hours of visitor arrival varied depending on the timing of the low tide. The weather and temperature also influenced the number of visitors. Although all dates fell within Japan's Golden Week holiday period, the designation of a day as a holiday varied depending on the company. 26 and 27 Apr were weekends, and 29 Apr was a national holiday, making it likely that more people were not working on those days.

The observations began before the peak arrival time and ended after most vehicles had departed. Table 1 lists the observation schedule, with low tide times sourced from the Higashi Hazu Fishery Cooperative and weather data. The maximum temperature (HIGH) and maximum hourly precipitation (MHP) were obtained from the nearest Japan Meteorological Agency station in Gamagori. All time notations in this study used the 24 h clock.

At the beginning of the observation period for each day, the number of parked vehicles were manually counted and

entered as the initial values. From this point onward, the system recorded the real-time vehicle count using the LiDAR sensor system described in Section 2.2.

Figure 5 illustrates the number of vehicles parked along the coast over five days. As expected, the highest numbers were recorded on 27 and 29 Apr, corresponding to the weekend and a national holiday, respectively.

Table 1. Vehicle count observation schedule

| Date       | 26 Apr | 27 Apr | 28 Apr | 29 Apr  | 30 Apr  |
|------------|--------|--------|--------|---------|---------|
| Days       | Sat    | Sun    | Mon    | Tue     | Wed     |
| Low tide   | 10:49  | 11:27  | 12:07  | 12:47   | 13:29   |
| HIGH (°C)  | 22.0   | 24.4   | 22.8   | 18.0    | 25.4    |
| MHP (mm)   | 0.0    | 0.0    | 4.0    | 0.0     | 0.0     |
| Obs. start | 11:46  | 08:11  | 08:07  | 08:08   | 07:58   |
| Obs. end   | 14:58  | 15:40  | 14:37  | 15:55   | 16:06   |
| VMS        | With   | With   | With   | Without | Without |

Figure 5. Result of the vehicle count observations

Across all observation days, the number of parked vehicles consistently plateaued at approximately 320, indicating that this range likely represents the maximum parking capacity of the seaside parking area. Furthermore, the peak time shifted later each day. This trend closely followed the shifting low tide times, as indicated in Table 1, suggesting that visitors timed their arrival to coincide with optimal clamming conditions.

Overall, the vehicle count results obtained using the LiDAR system reflected reasonable trends following the holiday calendar and tidal patterns. These results confirmed the effectiveness and reliability of the LiDAR-based vehicle counting methodology during the study period.

#### 3.2 Accuracy of the Vehicle Counting

This section presents a comparative analysis using video clips from exact angles to evaluate the accuracy of the vehicle counting using LiDAR sensors. A video camera was used to capture each of the two LiDAR sensors (L1 and L2) during the designated observation periods listed in Table 2. The L1 sensor, in particular, was

1 expected to face greater detection challenges owing to its  
2 complex location; therefore, video recording was  
3 conducted over a longer period.

4  
5 Manual vehicle counting using the video clips  
6 provided the ground truth, that is, the total number of  
7 vehicles entering and exiting during each observation  
8 interval. These values were then compared with the  
9 LiDAR results for the same time intervals to calculate the  
10 accuracy rate (AR).

11  
12 Table 2. Accuracy verification of vehicle counting with LiDAR

| Sensor | Date & Time        | Video | LiDAR | AR (%) |
|--------|--------------------|-------|-------|--------|
| L1     | 27 Apr 08:18-09:13 | 85    | 67    | 78.8   |
| L1     | 27 Apr 11:32-12:53 | -25   | -22   | 88.0   |
| L1     | 28 Apr 09:41-10:17 | 50    | 45    | 90.0   |
| L1     | 29 Apr 08:25-10:25 | 198   | 154   | 77.8   |
| L2     | 27 Apr 09:48-10:48 | 12    | 12    | 100    |
| L2     | 27 Apr 11:44-12:14 | -7    | -7    | 100    |

13  
14 As shown in Table 2, the L2 sensor achieved perfect  
15 accuracy (100%) over a total observation time of 90 min.  
16 This result confirmed that the LiDAR system functioned  
17 reliably and precisely at this location. Each counting  
18 result was the aggregate number of vehicles entering and  
19 exiting the seaside parking area. A positive value  
20 indicated that entering vehicles exceeded exiting vehicles.

21  
22 In contrast, the L1 sensor was closer to the clamming  
23 site, resulting in higher traffic volumes and a greater  
24 number of pedestrians. In addition, during periods of  
25 congestion, vehicles traveling in opposite directions often  
26 exhibit complex behaviors, including deadlocks and  
27 yielding on narrow streets. Owing to these factors,  
28 accurate observation of the L1 sensor location was  
29 technically challenging. On the mornings of 27 and 29  
30 Apr, both periods with a high visitor volume, the accuracy  
31 dropped to approximately 77–78%.

32  
33 There were three main factors that reduced the  
34 accuracy during these peak periods:

- 35 • High traffic densities resulted in short headways  
36 between vehicles, occasionally causing the system to  
37 detect two or more cars as a single unit.
- 38 • Pedestrian interference, in which there was an  
39 overlapping movement between vehicles and  
40 pedestrians within the field of view of the sensor, led  
41 to misclassification.
- 42 • Complex vehicle maneuvers, such as vehicle  
43 deadlocks and yielding on the narrow street in front of  
44 the sensor.

45  
46 Despite these challenges, the L1 sensor maintained  
47 accuracy levels of approximately 88–90% during non-  
48 peak periods. The overall accuracy for L1 remained >  
49 77%, indicating that the system operated reasonably well,  
50 even under challenging conditions. We converted each  
51 observation in Table 2 into 30-minute intervals and

52  
53 conducted a paired t-test. The resulting p-value was 0.17,  
54 indicating no statistically significant difference between  
55 the LiDAR-based observations and the ground truth from  
56 video recordings. Combined with the L2 results, the  
57 system demonstrated overall performance comparable to  
58 that of prior LiDAR-based studies, which reported  
59 detection accuracies of 83–94% [18].

### 3.3 Impact of the Variable Message Sign on Driver Behavior

60  
61 As shown in Figure 5, on 27 and 29 Apr, the number  
62 of visitors reached the parking capacity. As listed in Table  
63 1, a VMS was available on 27 Apr but not on 29 Apr.  
64 Based on this setup, this section verifies the impact of the  
65 VMS by comparing driver behaviors between these two  
66 days. The VMS automatically operated in response to  
67 vehicle counts in the seaside parking area. Specifically,  
68 the following messages were displayed based on the  
69 number of parked vehicles: "Seaside Congested" when  
70 the count was > 170 cars, "Seaside Full" when the count  
71 was > 240 vehicles, and no display when the count was <  
72 170.

73  
74 According to the vehicle counting results, the  
75 congestion or full-capacity conditions corresponded to the  
76 periods listed in Table 3.

77 Table 3. Periods with VMS active and inactive for verification

| Date                      | 27 Apr                     | 29 Apr                     |
|---------------------------|----------------------------|----------------------------|
| VMS                       | With                       | Without                    |
| Low tide                  | 11:27                      | 12:47                      |
| Periods with 170–240 cars | 08:50-09:35<br>13:15-13:55 | 09:10-09:45<br>13:50-14:35 |
| Period under verification | 09:05-09:35                | 09:10-09:40                |
| Period with 240+ cars     | 09:35-13:15                | 09:45-13:45                |
| Period under verification | 09:45-10:15                | 09:45-10:15                |

78  
79 A T-junction intersection was targeted by the VMS to  
80 reduce entry into the narrow road segment. At this  
81 intersection, the incoming vehicles could follow the paths  
82 illustrated in Figure 3 and were categorized as follows  
83 (Figure 6):

- 84 • *A*: Entering from the west and moving straight.
- 85 • *A'*: Entering from the west, signaling a right turn, but  
86 moving straight.
- 87 • *B*: Entering from the west and turning right.
- 88 • *B'*: Entering from the west and making a U-turn.
- 89 • *C*: Entering from the east and moving straight.
- 90 • *C'*: Entering from the east and making a U-turn.
- 91 • *D*: Entering from the east and turning left.

92  
93 Additionally, a *p* suffix indicates vehicles parked in the  
94 fringe parking (P2) as follows:  $A_p$ ,  $A'_p$ , and  $C'_p$ . Among  
95 these,  $A'_p$  and  $C'_p$  are of particular interest, as they likely  
96 represent drivers who initially intended to park at the main

seaside lot (P1) but diverted to P2 upon reaching the intersection.

Figure 6. Definition of incoming routes to the target intersection

Table 4 compares the number of  $A'_p$  and  $C'_p$  route users under the "Congested" and "Full" conditions, both with and without the VMS: For  $A'_p$ , the number of vehicles following this route increased both under congestion and full capacity when the VMS was present. For  $C'_p$ , an increase was observed under congested conditions when the VMS was active.

Although the number of observed vehicles was relatively small, these results suggest that the VMS effectively encouraged drivers to divert to the fringe parking lot (P2) when the seaside lot (P1) was congested or full.

Table 4. Number of vehicles diverted to the fringe parking

| Route  | Status    | Without VMS | With VMS |
|--------|-----------|-------------|----------|
| $A'_p$ | Congested | 1           | 5        |
|        | Full      | 11          | 16       |
| $C'_p$ | Congested | 0           | 4        |
|        | Full      | 5           | 5        |

Table 5. Proportion of fringe parking users among all traffic

| Status            | Congested |      | Full    |      |
|-------------------|-----------|------|---------|------|
|                   | Without   | With | Without | With |
| VMS               |           |      |         |      |
| P2 users          | 8         | 29   | 21      | 38   |
| All traffic       | 175       | 206  | 176     | 226  |
| P2 user ratio (%) | 4.6       | 14.1 | 11.9    | 16.8 |

Table 6. Proportion of fringe parking users among visitors

| Status            | Congested |      | Full    |      |
|-------------------|-----------|------|---------|------|

| VMS               |           |      |         |      |
| P2 users          | 6         | 28   | 17      | 36   |
| Non-P2 users      | 66        | 58   | 40      | 55   |
| P2 user ratio (%) | 8.3       | 32.6 | 29.8    | 39.6 |

Table 7. Proportion of fringe parking users (eastbound) among visitors

| Status            | Congested |      | Full    |      |
|-------------------|-----------|------|---------|------|
|                   | Without   | With | Without | With |
| VMS               |           |      |         |      |
| P2 users          | 6         | 24   | 16      | 31   |
| Non-P2 users      | 39        | 36   | 18      | 34   |
| P2 user ratio (%) | 13.3      | 40.0 | 47.1    | 47.7 |

Among all defined trajectories,  $A_p$ ,  $A'_p$ , and  $C'_p$  represent vehicles that used the fringe parking (P2). As this study focused on the number of fringe parking users among all traffic volumes at the intersection, its ratio increased in both the congestion and full cases when the VMS was activated (Table 5). In particular, under congestion, the increase was statistically significant at the 1% level according to a chi-square test.

In addition, the following were considered likely to be clamping visitors:  $A_p$ ,  $A'_p$ ,  $B$ ,  $C'_p$ , and  $D$ . The proportion of vehicles using P2 among the assumed clamping visitors was calculated (Table 6). The results showed that the proportion of fringe parking users was significantly higher when the VMS was active under the "Congested" conditions, with a chi-square test indicating statistical significance at the 0.1% level. The trend was the same under the "Full" condition; however, the difference was not statistically significant at the 10% level.

Additionally, given the location of the VMS and fringe parking, its influence was expected to be particularly strong for vehicles approaching from the west (eastbound). Therefore, the ratio of fringe parking users among the eastbound vehicles for clamping ( $A_p$ ,  $A'_p$ , and  $B$ ) was analyzed separately (Table 7). Under congested conditions, the VMS again resulted in a significantly higher proportion of fringe lot users, with the chi-square test confirming significance at the 1% level. Under the full condition, no significant difference was found at the 10% level, whereas the trend was the same as that in the congested condition.

## 4 Discussion

Implementing the VMS, which dynamically displayed the congestion status of the seaside parking lot, resulted in an increased number of vehicles diverting to from the narrow street to the fringe parking. This effect was observed during both "Congested" and "Full" conditions (Table 4).

These findings indicate that drivers changed their parking choices in response to the VMS display. Focusing on the proportion of all clamping visitors, the proportion of vehicles that chose the fringe parking was higher when the VMS was active in all cases (Tables 5-7). In contrast, the difference in the installation of the VMS was statistically significant only under the "congested" condition. These trends were consistent, regardless of whether the analysis included all directions or explicitly focused on eastbound vehicles, where the VMS was likely to have a more substantial influence.

One possible explanation for this difference is the observable state of the narrow street under the full-capacity condition. The narrow link often became visibly

1 congested when the lot was full because of cruising  
 2 vehicles and increased pedestrian activity. In such a  
 3 scenario, drivers may have chosen to divert to the fringe  
 4 lot, regardless of the presence of the VMS. Although there  
 5 was no significant difference between the with-VMS and  
 6 without-VMS cases, the overall diversion rate to the  
 7 fringe parking was higher under full-capacity conditions  
 8 than under congested conditions. In contrast, the narrow  
 9 street may not have appeared congested during congestion  
 10 but before reaching full-capacity. Therefore, the VMS  
 11 effect was more pronounced, with a more evident  
 12 influence on behavior.  
 13

14 There are several potential reasons why the effect of  
 15 the VMS on traffic volume reduction was limited,  
 16 including variations in visitor characteristics across  
 17 different periods. However, the content and format of the  
 18 VMS display itself may also have influenced driver  
 19 behavior. Under the general policy direction of the police,  
 20 real-world implementation of a VMS is often limited to  
 21 providing information rather than issuing behavioral  
 22 directives, which was also the case in this study. As such,  
 23 the strength of the behavioral impact of signage may be  
 24 inherently limited. Furthermore, owing to the technical  
 25 limitations of the VMS in this experiment, while  
 26 providing real-time information on seaside congestion, no  
 27 explicit indication of alternative parking options (e.g.,  
 28 location of the fringe parking lot) was available. This may  
 29 have restricted the range of viable decisions for first-time  
 30 visitors upon seeing the "Congested" or "Full" messages.  
 31 Given that messages displayed on VMS are more  
 32 effective when they provide specific context alongside  
 33 actionable guidance [21], the content presented in this  
 34 study still has room for improvement.  
 35

## 36 5 Conclusion

37  
 38  
 39  
 40 This study conducted a field experiment in Apr 2025  
 41 to evaluate the impact of a VMS parking guidance system  
 42 with LiDAR sensors aimed at reflecting the local traffic  
 43 issues caused by private vehicles visiting the Higashi-  
 44 Hazu Beach in Nishio City, Japan.

45  
 46 For real-time monitoring of parked vehicles, which  
 47 served as the basis for the guidance system, a sensing  
 48 setup was implemented utilizing only two LiDAR sensors,  
 49 drawing on autonomous vehicle technologies. The system  
 50 successfully enabled directional vehicle counting, and the  
 51 accuracy of these counts was validated through a  
 52 comparison with manual video observations, confirming  
 53 an acceptable level of reliability.

54  
 55 Based on the real-time parking counts, the system  
 56 dynamically displayed the congestion status ("Congested"  
 57 or "Full") of the seaside parking lot on a VMS installed at  
 58 the intersection to a narrow link. The system functioned  
 59 as expected during the demonstration period.

 65

Changes in driver behavior were observed, with some  
 vehicles diverting to the fringe parking instead of entering  
 the narrow street when the VMS displayed messages.  
 Furthermore, during congested periods, the proportion of  
 cars choosing the fringe parking lot was significantly  
 higher when the VMS was active, providing clear  
 evidence for the guidance effect.

These findings confirm that dynamic guidance based  
 on real-time parking data can be practical for influencing  
 driver decisions. However, during full-capacity periods,  
 the presence of the VMS did not lead to statistically  
 significant differences in driver behavior. It should be  
 noted that this study assessed effectiveness based solely  
 on the vehicle trajectory and did not include direct  
 feedback from drivers through interviews or surveys.  
 Therefore, understanding how drivers perceive  
 information was a limitation of this study.

The compact detection and guidance system validated  
 in this study, which is based on a minimal LiDAR sensor  
 infrastructure, has the potential to offer a practical  
 solution for addressing traffic issues arising under spatial  
 and temporal constraints. Unlike conventional methods,  
 which often require large-scale infrastructure, the  
 proposed approach is more appropriately scaled and  
 readily deployable for real-world applications.

## Abbreviations

MHP: Maximum Hourly Precipitation  
 VMS: Variable Message Sign  
 LiDAR: Light Detection and Ranging

## Statements and Declarations

**Competing Interests:** The authors declare that they have  
 no known competing financial interests or personal  
 relationships that could have appeared to influence the  
 work reported in this paper.
